Report on

the Assessment of

the Geographical BSE-Risk (GBR) of

SPAIN

July 2000

NOTE TO THE READER

Independent experts have produced this report, applying an innovative methodology by a complex process to data that were voluntarily supplied by the responsible country authorities. Both, the methodology and the process are described in detail in the final opinion of the SSC on "the Geographical Risk of Bovine Spongiform Encephalopathy (GBR)“, 6 July 2000. This opinion is available at the following Internet address:

<http://europa.eu.int/comm/food/fs/ssc/out113_en.pdf>

In order to understand the rationale of the report leading to its conclusions and the terminology used in the report, it is highly advisable to have read the opinion before reading the report. The opinion also provides an overview of the assessments for another 24 countries.
PART I

Description of the method and its limitations, and definitions and process used for assessing the GBR of SPAIN
1. INTRODUCTION

The Geographical BSE-Risk (GBR) is a qualitative indicator of the likelihood of the presence of one or more cattle being infected with BSE (Bovine Spongiforme Encephalopathy), pre-clinically as well as clinically, at a given point in time, in a country. Where its presence is confirmed, the GBR gives an indication of the level of infection.

This opinion describes a transparent methodology that the Scientific Steering Committee (SSC) has developed, over about two years, to assess the GBR for any country that provides the information required for the assessment. This methodology is limited to bovines and feed based transmission of BSE. It does not take into account any other initial sources of BSE than the import of infected cattle or contaminated feed. It is assumed that the disease first appeared in the UK from a still unknown initial source. An important characteristic of the methodology is that it does not depend on the confirmed incidence of clinical BSE, which is sometimes difficult to assess due to serious intrinsic limitations of surveillance systems. The other advantage of this methodology is that it allows an easy identification of possible additional measures that in a given situation may improve the ability of a country to cope with BSE.

The qualitative nature of this methodology and its limitations should be understood in the context of present scientific knowledge on BSE and of the availability and quality of data. As they both evolve, and with the possible advancement of diagnostic methods, the need may arise for the methodology to be revised and/or its application to particular countries to be repeated.

In parallel with the work of the SSC, the OIE (Office International des Epizooties) has developed further the BSE-chapter in its Animal Health Code, which makes reference to risk analysis as an integrated part of the procedure to establish the BSE-status of countries or zones. The compatibility of the OIE approach and the SSC methodology for assessing the GBR is extensively discussed in this opinion.

The present opinion also describes the highly interactive procedure through which the methodology has been applied to those countries that have submitted information and data so far, and the results of this application.

The SSC wants to underline that its main task is to assess whether the presence of one or more infected cattle in a given country is « highly unlikely », « unlikely, but not excluded », « likely, but not confirmed », or « confirmed at lower or higher level » and what the future trend might be. In making this assessment, the SSC has used a reasonable worst-case approach (i.e. a conservative approach) every time data availability was insufficient.

---

1 Surveillance should be understood as the process of identifying BSE-cases and animals at risk of being infected.
It should be clear that the GBR has no direct bearing on human exposure to BSE. In fact, at a given GBR, the risk that food is contaminated with the BSE agent depends on three main factors:
- the likelihood that infected bovines are processed;
- the amount and distribution of infectivity in BSE-infected cattle at slaughter; and
- the ways in which the various tissues that contain infectivity are processed.

Also the risk that animals are exposed to the BSE agent is strongly influenced by a range of other parameters.

The SSC believes that decisions aimed at managing the BSE-risk are the responsibility of the authorities in charge and might need to take into account other aspects than those covered by this risk assessment.

**2. THE GEOGRAPHICAL BSE-RISK (GBR) - METHODOLOGY AND PROCEDURE**

**2.1 DEFINITION OF THE GEOGRAPHICAL BSE-RISK (GBR)**

The Geographical BSE-Risk (GBR) is a qualitative indicator of the likelihood of the presence of one or more cattle being infected with BSE, pre-clinically as well as clinically, at a given point in time, in a country. Where presence is confirmed, the GBR gives an indication of the level of infection as specified in the table below.

<table>
<thead>
<tr>
<th>GBR level</th>
<th>Presence of one or more cattle clinically or pre-clinically infected with the BSE agent in a geographical region/country</th>
</tr>
</thead>
<tbody>
<tr>
<td>I</td>
<td>Highly unlikely</td>
</tr>
<tr>
<td>II</td>
<td>Unlikely but not excluded</td>
</tr>
<tr>
<td>III</td>
<td>Likely but not confirmed or confirmed, at a lower level</td>
</tr>
<tr>
<td>IV</td>
<td>Confirmed, at a higher level</td>
</tr>
</tbody>
</table>

Table 1 - Definition of GBR and its levels

The SSC is well aware that the borderline between GBR level III and IV has to remain arbitrary, as no clear scientific justification can be provided for this differentiation. The SSC adopts for the time being the OIE threshold, i.e. an incidence of more than 100 confirmed BSE cases per million within the cattle population over 24 months of age in the country or zone, calculated over the past 12 months.

The SSC also agrees with the OIE (see also section 2.6 of this document) that, under certain circumstances, countries with an observed domestic incidence between 1 and 100 BSE-cases per million adult cattle calculated over the past 12
months, should be put into the highest risk level if, for example, there are clear indications that the true clinical incidence is in fact higher than 100 per million adult cattle calculated over the past 12 months.

Active surveillance exercises in Switzerland (of adult cattle not notified as BSE or CNS suspect in fallen stock, emergency slaughter, and normal slaughter) and the UK (OTMS-survey) both detected several confirmed BSE-cases that would have remained undetected by normal, passive surveillance, even if targeted at animals with neurological symptoms. The SSC therefore assumed that passive surveillance does not give a true estimate of the existing BSE-cases. The Swiss and UK results indicate that it is likely that passive surveillance, based solely on notification of symptomatic BSE-suspects, will not detect more than half or one third of all clinical cases, or even fewer. However, as long as it is impossible to detect pre-clinical cases in the early phases of the incubation period, active surveillance of apparently healthy animals younger than 24 months cannot be expected to improve the detection level.

At this stage it should be reiterated that the applied 4 GBR-levels are only used to illustrate in qualitative terms different risk levels. Each of these levels includes a range of different potential risks. This range is not considered in the current classification.

### 2.2 Methodology for Assessing the GBR

#### 2.21 Basic assumptions

The present application of the SSC-methodology for the assessment of the GBR is based on the assumption that BSE arose in the United Kingdom (UK) and was propagated through the recycling of bovine tissues into animal feed. Later the export of infected animals and infected feed provided the means for the spread of the BSE-agent to other countries where it was again recycled and propagated via the feed chain.

For all countries other than the UK, import of contaminated feed or infected animals is the only possible initial source of BSE that is taken into account. Potential sources such as a spontaneous occurrence of BSE at very low frequency or the transformation into BSE of other (animal) TSEs (scrapie, CWD, TME, FSE) being present in a country are not considered, as they are not scientifically confirmed.

---

2 Active surveillance = testing of cattle that are not notified as BSE-suspects but belong to risk sub-populations.
3 OTMS=Over Thirty Months Scheme. This scheme excludes all cattle older than 30 months from the animal feed and human food chain. The survey involved sampling about 3000 cattle older than 60 months and which did not show any symptoms compatible with BSE and found 18 BSE-cases.
4 Passive surveillance = surveillance of notified BSE-suspects, i.e. cattle that are notified because of clinical signs compatible with BSE.
5 TSE=Transmissible Spongiform Encephalopathy; CWD=Chronic Wasting Disease; TME=Transmissible Mink Encephalopathy; FSE=Feline Spongiform Encephalopathy
The only transmission mode considered in the model is feed. Contaminated feed is taken as the only possible route of infection because epidemiological research showed clearly that the origin and maintenance of the BSE epidemic in the UK was directly linked to the consumption of infected meat and bone meal by cattle. Blood, semen and embryos are not seen to be effective transmission vectors. Accordingly, blood-meal is not taken into account, neither.

During the assessment, it became obvious from different sources that cross-contamination of MMBM-free cattle feed with other feeds that contain such ingredients can be a way of propagating the disease. Therefore, it is important to understand that, as long as feeding of MMBM, BM (Bone meal) or Greaves to other farmed animals is legally possible, cross-contamination of cattle feed with animal (ruminant) protein can not be eliminated. Dedicated production lines and transport channels and control of the use and possession of MMBM at farm level would be required to fully control cross-contamination. It should be clear that any cross contamination of cattle feed with MMBM, even well below 0.5%, represents a risk of transmitting the disease. However, the influence of cross-contamination on the GBR has to be seen in the light of the risk that the animal protein under consideration could carry BSE-infectivity.

In the light of the qualitative nature of the exercise, its relatively lesser importance in comparison to feed, and the lack of final scientific confirmation of its existence, the possible impact of maternal transmission on the GBR has not been taken into account in this methodology.

Similarly no “third route of transmission” was taken into account. The existence of a third mode of transmission of BSE, in addition to feed and vertical transmission, such as horizontal transmission via the environment, cannot be excluded. However, to date there is no scientific evidence for such a third potential mode of transmission. The assessment also does not take into account the possibility that sheep and goats may have become infected with BSE.

The present GBR risk assessments (see chapter 3 and annex III) are only addressing entire countries and national herds. This is because of the limited availability of detailed, regionalised data. The SSC does not discount the issue of regional differences, for example in the types of animal husbandry e.g. dairy or beef, of feeding or of slaughtering ages. If complete data sets were to be provided on a regional scale, i.e. clearly relating to a defined geographical area, these could be assessed in the same way as data referring to entire countries.

---

6 See SSC-opinion on vertical transmission, 18-19 March 1999 and on the safety of ruminant blood (13/14 April 2000)
7 MMBM = Mammalian MBM
8 In its opinion on cross-contamination (n° 12 in annex I) the SSC already expressed this position.
9 There are statistical indications that the disease may be vertically transmitted from dam to calf. It was statistically shown that the risk of maternal transmission occurring is higher if the calf was born within 6 months before the onset of the clinical signs in the dam. Offspring cull and assurance that the dam has survived without BSE for at least six months after calving will thus provide a certain degree of assurance that its offspring is safe (see Opinions N°s 2, 4, 23, 24 and 30 listed in Annex 1).
10 See SSC-opinions N°s 4, 23, and 30 listed in Annex 1
11 See SSC opinion on the risk of infection of sheep and goats with BSE, 24/25 September 1998
2.22 Information factors and model of the BSE cattle system

The methodology is based on information on 8 factors that were originally identified by the SSC in January 1998. In table 2 the most relevant information is listed that was finally found to be important for carrying out the assessment.

Table 2 – Information factors for assessing the GBR Note: all information should be available for the period from 1980 onwards and be presented on an annual base. For the purpose of the GBR-assessment reasonable worst case assumptions have been used whenever the information was not complete.
In order to clarify the (often-delayed) interaction between these factors, the SSC has adopted a simplified strictly qualitative model of the cattle/BSE system\(^{12}\) (Figure 1) which focuses on the feed-back loop that needs to be activated to spark a BSE-epidemic. This feed-back loop consists essentially of the processing of (parts of) cattle that carry the BSE-agent into feed and the feeding of this to cattle who then get infected and multiply the BSE-agent inside their bodies leading to very different concentration of infectivity in different tissues.

This feed-back loop is influenced by a number of factors that, on the one hand, may activate the loop and, on the other hand, might prevent this activation or slow down or reverse the building up of BSE-infectivity within the system.

In the model used by the SSC the initial introduction of the BSE-agent has to come from outside – it is therefore called an external challenge of the system\(^{13}\). Two possible routes of introduction are considered: import of infected cattle or import

---

\(^{12}\) A BSE/cattle system of a country or region comprises the cattle population and all factors that are of relevance for the propagation of the BSE-agent, should it be present within its boundaries. The model used by the SSC to describe this system is presented in figure 1, it is a deliberately kept simple.
of contaminated MBM.

The factors assumed to be able to prevent the building-up of BSE-infectivity in the system are the following:

- **Surveillance and culling.** By identifying BSE-cases (by passive and active surveillance including testing and laboratory confirmation) and excluding them and related cattle at risk of being infected from processing (by “culling” and destruction), the risk of introducing the BSE-agent into the feed chain is reduced.

- **SRM-removal.** By excluding those tissues known to carry the bulk of the infectivity that can be harboured by a (pre-)clinical BSE-case from rendering, it reduces the infectivity that could enter the feed chain. Excluding fallen stock from the feed chain is seen to be equally effective as a “partial” SRM-ban because, according to Swiss experience, the frequency of infective (pre-) clinical cases in fallen stock seems to be higher than in normal slaughter.

- **Rendering.** Appropriate rendering processes reduce BSE-infectivity that is carried by the raw material by a factor of up-to 1,000 (see footnote 14).

- **Feeding.** By ensuring that no feed that could carry the BSE-agent reached cattle this effectively reduces the risk of new infections in the domestic cattle population.

In summary, the model basically can be broken down into two parts relating to challenge (chapter 2.23 and 2.25) and stability (chapter 2.24). The model assumes a mechanism for their interaction.

### 2.23 External challenge

The term “external challenge” is referring to both the likelihood and the amount of the BSE agent entering into a defined geographical area in a given time period through infected cattle or MBM.

#### 2.231 Assessing the external challenge

During the GBR-assessment exercise it became necessary to establish guidelines for assessing the external challenge in order to ensure that comparable challenges were always assessed similarly.

To this end it was first decided to regard the external challenge independent from the size of the challenged BSE/cattle system and in particular the size and structure of the total cattle population (see also section 2.25)

Secondly, it was decided to use the assumed challenge resulting from imports from the UK during the peak of the BSE-epidemic in the UK as the point of reference and to establish the challenge resulting from imports during other periods and from other BSE-affected countries in relation to this baseline.

---

13 For the UK it is assumed that the initial introduction of the agent happened before the period taken into account in this model.

14 See SSC-opinion on the Safety of Meat and Bone Meal, 26/27 March 1998
Therefore, the figures given in table 3 below refer to imports from the country (UK) and the period of time where the risk of contamination of exports with the BSE-agent was regarded to be highest. For live cattle imports this was assumed to be the period 1988 to 1993. As a reasonable worst case assumption it was assumed\textsuperscript{15} that during this period the average BSE-prevalence of infected animals in exported cattle was around 5\%\textsuperscript{16}, i.e. of 20 animals one could have been infected. Therefore, a moderate external challenge would have made it likely that at least one infected animal was imported. The other levels of external challenge were established with the intention of indicating differences from this level of potentially imported infection.

The assessment of the challenge posed by MBM imports (also table 3) were similarly chosen in accordance with the following events and steps:

- The critical period, i.e. the period of highest risk that MBM imports from the UK were contaminated was set to 1986 –1990. This is the period with the highest case incidence in the birth cohorts.

- The risk peaked in 1988 when SBO\textsuperscript{17} were excluded from the human food chain but included into rendering and feed production. It was reduced with the exclusion of SBO\textsuperscript{11} from rendering at the end of 1989.

- The table below indicates that the import of one ton of MBM is seen to pose the same challenge as the import of one live animal. This is justified by the fact that available import statistics do not allow the differentiation between different forms of animal proteins and that practically all MBM produced in Europe is always a mixture of ruminant and non-ruminant material. It should also be seen in the context that the probability that more than one infected cattle was processed per ton of final MBM is very low, even in the UK\textsuperscript{18}.

\textsuperscript{15} The period 88-93 was chosen as highest risk period for live cattle imports because it covers the period of roughly one incubation period before the highest incidence (1992/93). Recent data on case incidence in birth cohorts show that this was already high in 1985/86 and 1986/87. However, as cattle are normally exported at an age between 6 (veal) and 24 (breeding stock) months, it was felt justified to keep this range. Nevertheless it might be possible that the risk carried by imports in 1987 was slightly underestimated by this approach.

\textsuperscript{16} The value of 5\% was used because at normal survival probabilities only one in 5 calves reaches an age of 5 years. If the case incidence in a birth cohort was about 1\%, about 5\% of the calves in that birth cohort could have been infected.

\textsuperscript{17} Specified Bovine Offal = those bovine offal that contain the highest concentration of BSE-infectivity in a clinical BSE-case.

\textsuperscript{18} As one cattle carcass is rendered into about 65 kg MBM, 18 carcasses would be needed per ton of MBM.
In other countries affected by BSE and, in the UK, at other periods the risk that exported cattle were carrying the BSE-agent or that MBM was contaminated with BSE was lower. Accordingly the challenge posed by the same amount of imports would be much lower or the same level of challenge would only occur at higher imports. To adapt the thresholds accordingly, the following multipliers were used:

- **Import from UK in other periods:**
  - **Cattle:** before 1988 and from 1994 to 1997: multiply all thresholds by 10; 1998 and after: multiply all thresholds by 100;
  - **MBM:** before 1986 and from 1991 to 1993: multiply all thresholds by 10; 1993 and after: multiply all thresholds by 100.

- **Import from other countries than UK affected by BSE:** regardless of period and whenever there is reason to assume that BSE was already present at time of export:
  - **Cattle:** multiply all thresholds by 100.
  - **MBM:** multiply all thresholds by 10.

It has to be underlined that the above figures in the table and the multipliers are only indicative. It is obvious that the final external challenge associated with imported cattle and their impact will largely depend of a number of factors including their age at slaughter. Excluding imported animals from the feed chain would reduce the challenge that the excluded animals represent to a negligible level. Accordingly imported animals that are slaughtered before reaching an age of 24 months would represent a lower challenge than imported animals used for breeding and then rendered at an age high enough to be approaching the end of the incubation period. If available, this and similar information are used to modulate the criteria in the table.

### 2.24 Stability

**Stability** is defined as the ability of a BSE/cattle system to prevent the introduction and to reduce the spread of the BSE agent within its borders. Stability relies on the avoidance of processing of infected cattle and the avoidance of recycling of the...
BSE agent via the feed chain. A “stable” system would eliminate BSE over time; an “unstable” system would amplify it.

The most important stability factors are those which reduce the risk of recycling of BSE, in particular:
- avoiding feeding of MBM to cattle,
- a rendering system (“rendering”), able to largely inactivate BSE-infectivity (e.g. by applying “standard 19” treatment at 133°/20 min/3 bar), and
- exclusion of those tissues/organs from rendering where BSE infectivity could be particularly high (“SRM-removal”). Excluding fallen stock from the feed chain will also reduce the amount of BSE infectivity that could enter the feed chain and is necessary for a fully efficient SRM-removal. Excluding fallen stock from rendering alone, i.e. without exclusion of SRM from other cattle, would have some effect but is not as efficient as a “reasonably OK” system of SRM-removal.

A comprehensive surveillance system (including passive and active elements) and related activities that ensure detection and isolation (and destruction) of BSE-cases and cattle at risk of being infected would also enhance the stability of the system.

These stability factors were already relevant before their contribution to prevent spreading the BSE epidemic was scientifically understood. It is therefore clear that even compliance with a regulation that at that time was scientifically up-to-date may not always have guaranteed stability.

2.241 Stability levels

A BSE/cattle system can only be regarded to be “optimally stable” if all three main stability factors (feeding, rendering, SRM-removal including fallen stock) are in place, well controlled, implemented and audited (“OK”). Ideally such a system would also exclude fallen stock from processing into feed and integrate a highly effective capacity to identify BSE-cases and exclude them together with cattle at risk of being infected from being processed. Such a system would fully prevent propagation of BSE-infectivity and eliminate BSE-infectivity from the system very fast.

If two of the three factors are assessed to be “OK” but one of these factors is only reasonably implemented (“reasonably OK”), the system could at best be assumed to be “very stable”. Propagation would be largely prevented but the elimination of BSE-infectivity from the system is slower than in an “optimally stable” system.

A system can still be assumed to be “stable” as long as two of the three factors are “OK”, or one is “OK” and two are “reasonably OK”. BSE will be eliminated from the system over time but propagation may still take place – only at a lower rate than the elimination of BSE from the system.

If all three factors are “reasonably OK”, the system can nevertheless only be assessed as “neutrally stable”, i.e. it would neither amplify nor reduce circulating

---

19 As defined in the SSC-opinion on MBM, see n°8 in annex 1
BSE-infectivity over time. The same is true if only one factor is “OK” and two are not present or only badly implemented.

If only two factors are “reasonably OK”, the system is seen to be “unstable”. It will amplify BSE, should it be introduced. This means the propagation rate is higher than the elimination rate, if there is any.

With only one “reasonably OK” factor in place, the system is assumed to be “very unstable”, i.e. recycling a large proportion of the BSE-agent and propagating the disease rather fast.

If none of the three factors can even be considered as “reasonably OK”, the system would be “extremely unstable”, quickly propagating the BSE-agent, should it enter, and amplifying the BSE-load of the system.

These considerations are summarised in table 4 below that was used as guidance for ensuring comparability of approaches used for assessing the degree of stability of a given BSE/cattle system between the different country assessments.

</tbody>
</table>

Table 4: BSE-stability levels (*“Optimally” should be understood as “as good as possible according to current knowledge”.)

Explanation concerning the three main stability-factors:

**Feeding:**
OK = evidence provided that it is highly unlikely that any cattle received MMBM.
Reasonably OK = voluntary feeding unlikely but cross contamination cannot be excluded.

**Rendering:**
OK = only plants that reliably operate at 133⁰/20min/3bar-standard.
Reasonably OK = all plants processing high-risk material (SRM, fallen stock, material not fit for human consumption) operating at 133⁰/20min/3bar – standard, low-risk material is processed at more gentle conditions.
SRM-removal: OK = SRM-removal from imported and domestic cattle in place, well implemented and evidence provided. Fallen stock is excluded from the feed chain. Reasonably OK = SRM-removal from imported and domestic cattle in place but not well implemented or documented. If in addition to a “reasonable OK” SRM-removal fallen-stock is excluded from rendering, the “SRM-removal” might be considered “OK”. Exclusion of fallen stock from rendering alone is regarded to be useful but not as effective as a “reasonably OK” SRM-removal.

**Note:** Surveillance and culling are essential for the ability of a system to identify clinical BSE-cases and to avoid that they, and related at-risk animals, enter processing. A good surveillance system can therefore, in combination with appropriate culling, improve the stability by supporting the exclusion of BSE-infectivity from the system. It would, however, not be sufficient to make a system more stable (move it into the next higher stability level) than it would be due to the three main stability factors.

### 2.25 Internal challenge

The term “internal challenge” is referring to the likelihood and the amount of the BSE-agent being present and circulating in a specific geographical area in a given time period.

If present, the agent could be there in infected domestic animals, where it would be replicated, in particular in SRMs, and in domestic MBM made from the infected domestic cattle. The internal challenge in a given period is a consequence of the interaction of the stability of the system and the combined external and internal challenge to which it was exposed in a previous period.

- If a fully stable BSE/cattle system is exposed to an external challenge, processing and recycling of the BSE-load entering the system will be prevented and the infectivity load will be neutralised over time. No internal challenge will result from this external challenge because the system is able to cope with it.

- If an unstable BSE/cattle system is exposed to an external challenge, processing and recycling of the BSE-load entering the system will take place and the agent will start circulating in the system. It will first be present in contaminated domestic MBM and, if this is fed to domestic cattle, these are likely to become infected. After approximately another 5 years (average incubation period) a certain number of them, which have survived until that age, could become clinical-BSE cases. Others might be processed before developing clinical symptoms and the infectivity harboured by them will again be recycled. By this way the internal BSE-load of the system is going to be amplified and a BSE-epidemic could develop (see fig.2).

The number of domestic cattle that are pre-clinically or clinically infected with the BSE-agent while being alive in the system at a given point in time could be taken as an indicator of the size of the internal challenge. However, it is currently impossible to detect pre-clinical BSE-cases and early clinical phases of BSE are
easily misdiagnosed. Therefore the time frame required for an internal challenge to be detected in an unstable country challenged by BSE will normally be at least one incubation period after the initial challenge (approximately 5 years). It may be much longer, depending on a number of factors including the following ones:

- the extent of the BSE challenge (a larger challenge would lead to more new infections with a higher number of cases reaching the clinical phase);
- the extent of the instability of the country (a very unstable system would amplify the infectivity faster and lead more rapidly to a higher number of cases);
- the size of the national cattle population (within a smaller population the same number of cases might be more easily discovered than in a large population, i.e. given a similar initial challenge and similar rates of propagation it would take longer to reach the same incidence level), animal demographics and agricultural and marketing practices of the challenged countries (e.g. if cattle are hardly reaching an age of 5 or more years, the probability that incubating animals turn into clinical cases is reduced); and
- the quality and validity of the BSE surveillance in the challenged country (the better the surveillance the earlier the detection as the risk of missing a case is smaller).

Depending on the many specifications of each case, detection of an internal challenge may take from a minimum of an average of 5 years from the initial challenge (average incubation period) up to several incubation periods. The longer periods might be valid because several cycles of about one incubation-period each are needed to reach numbers of clinical BSE-cases that are detectable by existing surveillance systems.

In principle, it cannot be excluded that, under certain circumstances, even an infectious load entering an unstable BSE/cattle-system may have no impact. This may happen if it is unintentionally eliminated, e.g. if contaminated imported MBM is all fed to pigs or poultry and does not reach cattle, even if during that period feeding MBM to cattle was legally possible and generally done. However, the SSC has assumed, as a reasonable worst case scenario, that exposure of an unstable system to the BSE agent would always result sooner or later in an internal challenge. The speed of this development depends on the degree of stability of the system.

### 2.26 Interaction of overall challenge and stability over time

The overall challenge is the combination of the external and internal challenges being present in a BSE/cattle system at a given point of time.

Four different basic combinations of stability and challenge can be seen.

- A “stable” system that is not or only slightly “challenged”: this is obviously the best situation.
- A “stable” system that is highly “challenged”: this is still rather good because the system will be able remove the BSE, even if this might need some time.
- An “unstable” system is not or only slightly “challenged”: as long as BSE is not entering the system, the situation is good. However, if BSE would enter the system it could be amplified.

- An “unstable” system is “challenged”: obviously this is an unfortunate situation. BSE-infectivity entering the system will be amplified and an epidemic will develop.

These “stability” and “challenge” situations are illustrated by the two-dimensional diagram given in Figure 2, where both axes spread between the respective lowest and highest feasible level.

![Stability/Challenge Combination Diagram](image)

**Figure 2: Stability/challenge combination, four principal situations and a hypothetical development over time**

Since the above-mentioned 8 factors, on which challenge (external and internal) and stability depend, change over time, it is necessary to assess the challenge and stability at different periods. These periods might, for example, be determined in function of changes of stability (e.g. by an MBM-ban) and/or challenge (e.g. preventing BSE from entering the system).

The arrows in figure 2 indicate an example for a hypothetical development over time. A very unstable system is exposed to a very low initial (external) challenge. Because of the low stability and as it is assumed that no special measures are taken to prevent the “dangerous” imports from entering the feed cycle, e.g. by putting the imported animals under strict monitoring and prohibiting them to be rendered, the BSE-infectivity is recycled and, over time, amplified. After some time (several years) the challenge (external plus internal) is reaching a moderate level but in the hypothetical example the stability is improving, too, for example by excluding ruminant MBM from cattle feed. The system, however, remains unstable and
therefore the BSE-infectivity that is present in the system continues to be recycled and amplified. A high challenge develops. Fortunately the stability of the system is increasing. As soon as it is stable the system eliminates BSE-infectivity and the challenge decreases (as long as no new external challenges occur). With a further improvement of the stability the decrease of the challenge will be quicker.

From the above explanations it becomes clear that the past stability and overall challenge of the system are the reason for the current internal challenge and hence the current GBR. The impact of most risk management measures on the number of clinical BSE-cases is delayed by at least one incubation period of BSE, in bovines on average 5 years. Therefore measures taken in the last five years may have had an immediate effect on the recycling and amplification of the BSE-agent and hence the internal challenge and the current GBR but will only be reflected in the number of clinical BSE-cases around one incubation period after their effective implementation.

It is also clear that the future development of the GBR is influenced by the occurrence of additional external challenges and the continued ability of the system to reduce any incoming or already existing BSE infectivity. Assuming that new challenges can be avoided, the current stability determines the slope of the GBR-trend. An optimally stable system will very quickly reduce the GBR-level and an extremely unstable system will very quickly amplify any BSE-infectivity that is already in the system and increase the GBR-level.

### 2.3 Procedure for Assessing the GBR

#### 2.3.1 Development of the methodology

In January 1998, the SSC established a list of factors on which it would require information for assessing the Geographical BSE-Risk (GBR)\(^{20}\).

In July 1998, the Commission recommended to Member States and interested Third Countries to provide information on these factors\(^{21}\).

In December 1998, the SSC issued a draft opinion on a method for assessing the Geographical BSE-Risk of a country or region. This was adopted in February 1999\(^{22}\), taking into account comments received and the method was first applied in March 1999 to 11 Member States of the European Union (MS) that had supplied dossiers at that time. The methodology and process were repeatedly updated. The basis for these updates was the experience gained with its application to 26 countries who had voluntarily submitted information and the comments received from several of these countries on

- the drafts of their reports (April/May and June 1999 and 2000),

\(^{20}\)Opinion of the SSC on defining the BSE-risk for specified geographical areas. 22/23 January 1998

\(^{21}\)Commission recommendation of 22 July 1998 concerning information necessary to support applications or the evaluation of the epidemiological status of countries with respect to TSEs. (C(1998) 2268): 98/ 447/EC)

\(^{22}\)Opinion of the SSC on a method to assess the Geographical BSE-Risk of countries or regions. 18-19/02/99

\(^{21}\)The reports for the Czech Republic, India and the Slovak Republic are still pending finalisation.
2.32 The process

The application of the SSC methodology was carried out with the help of about 50 independent experts, coming from most of the Member States and Third Countries.

More than three independent experts assessed each country and discussed their analyses with the country’s experts in order to clarify the available information. These discussions proved to be very valuable. To date, July 2000, twenty-three countries have been assessed.

The assessed countries have openly co-operated in the assessment by sending their country experts and by reacting to the draft reports forwarded to them for comments. During the process many countries provided additional information that improved the basis for the risk assessment.

The process by which the independent experts assessed the GBR of a given country is outlined in table 5. The report on the assessment of the GBR of each country followed the same scheme. The interaction of the countries was essentially contributing to the tasks in step 1 (data appreciation) and the appraisal of the appropriateness of the conclusions drawn and presented under the points 2-5.

Notwithstanding the efforts made to harmonise the approaches taken by the different experts, a certain degree of difference in appraisal of comparable data could not have been avoided. With a view to harmonise the different country reports and to ensure consistency a final review of all assessments was carried out from January 2000.

Having taken account of the draft country reports available in January 2000, the SSC charged 20 independent experts to review them. In order to do so they were asked to establish criteria for determining the respective degrees of stability and challenge of each country, and to apply these consistently to all assessments. The experts were also requested to apply a consistent approach to estimating the current and future GBR derived from the past and current interaction of stability and challenge.

---

24 In order to identify these independent experts the ad-hoc TSE/BSE group discussed the importance of the quality of the experts and developed a set of criteria that was subsequently adopted by the SSC (October 1998). Members of the ad-hoc group and of the SSC were invited to submit names and a list of possible candidates was established, also including experts known to the secretariat from previous work. This list was discussed at the TSE/BSE ad-hoc group and also given to the SSC. There were no objections to the list and it was left to the secretariat to invite the experts taking account of the selection criteria agreed on and the availability of the experts.
1. Appraisal of the quality of the available data

2. Assessment of the Stability of the BSE/cattle system (over time).
   2.1 Ability to identify BSE-cases & to exclude cattle at-risk of being infected from processing
   2.2 Ability to avoid recycling BSE-infectivity, should it enter processing
   2.3 Overall assessment of the stability (over time)

3. Assessment of the challenges to the system (over time)
   3.1 External challenge resulting from importing BSE
   3.2 Internal challenge resulting from the interaction of external challenge and stability.
   3.3 Overall assessment of the stability (over time)

4. Conclusion on the resulting risks (over time)
   4.1 Interaction of stability and overall challenge (over time)
   4.2 Risk that BSE-infectivity enters processing (over time)
   4.3 Risk that BSE-infectivity is recycled and the disease propagated (over time)

5. Conclusion on the Geographical BSE-Risk
   5.1 The current GBR as function of the past stability and challenge
   5.2 The expected development of the GBR as function of past and present stability & challenge
   5.3 Recommendations to influence the expected development of the GBR.

Table 5: - Outline for the assessment procedure established by the SSC and applied by the independent experts. This outline was also used to structure the Country reports.

In order to do so, the 20 independent experts:

- agreed on practical criteria of assessing challenge and stability to be used as "orientation" to avoid inconsistencies between countries and
- established guidelines for revising and harmonising the reports & their presentation and
- agreed on the current GBR-level and the expected trend for each of the countries assessed on the basis of the information available to them early in February 2000.

The reports that had been prepared by the 20 independent experts were then examined by the TSE/BSE ad-hoc-group and the SSC.

On 2/3 March 2000 the SSC indicated a general agreement with the assessments while still pinpointing to room for improvement in terms of consistency within and between reports and terminology-standardisation. The SSC also recognised the need to up-date them in the light of additional information that became available between May 1999 and early March 2000. It charged a small group of its members and some assessors to carry out this task, taking due account of comments received by the members of the TSE/BSE ad-hoc group, the SSC and the Commission services, which were also invited to comment on the factual correctness of the reports. Subsequently the reports were sent to the respective countries together with a copy of a draft of this opinion. Comments on both documents were requested from the countries by early May 2000. The comments received were taken into account for revising the methodology of the SSC for assessing the Geographical Risk of Bovine Spongiform Encephalopathy (GBR) and preparing preliminary versions of the country reports. It was assumed that countries, which did not submit comments, agreed to the provided documents.
On 25/26 May 2000 the SSC adopted the preliminary opinion and the preliminary GBR-country reports and requested their immediate publication on the Internet, inviting comments on both, the opinion and the reports, until 19 June 2000. Being aware of the sensitivity of the topic, the SSC made it clear that it would only consider comments related to the Risk-Assessment dimension of the issue, not those on the Risk-Management aspects.

The current final opinion and the related final GBR-country-reports take due account of the comments received. These documents now set out the SSC’s final views on both the methodology issues and the GBR in each country that has been considered.

In reviewing this opinion and the related country reports it should be understood that in the view of the SSC it is expected that the framework of analysis will need to be revised if novel findings emerge, i.e. this opinion is dynamic in process as more scientific evidence will be available. These may relate to the source of BSE, to the diagnosis and transmissibility of BSE or to the infective dose for man. It can also be expected that novel developments in surveillance and management techniques or new tests to assess the prevalence of sub-clinical BSE conducted in a country may also precipitate the need for a selective re-assessment of a particular GBR.

The SSC’s experience in assessing changes in the challenges and stability of countries, however, suggests that trends in incidence figures may allow different conclusions to be drawn only after 3 –5 years. In any case, the current assessments have to be up-dated from time to time.

### 2.4 Availability and Quality of Data

The SSC is well aware of the critical importance of the availability and quality of data for any risk assessment. It is, therefore, necessary to appreciate that the current GBR assessments are mainly based on information provided by the assessed countries and that it is essential to assume that the information provided is correct. In essence the provision of an appropriate basis for the GBR-assessment was the responsibility of the competent national authorities.

In general the available data were seen to be adequate to carry out the assessment of the GBR. Despite all efforts, however, considerable differences in the availability and quality of data remain of concern.

Additional sources of information, such as reports from the missions of the EC-Veterinary Inspection Services (the Food and Veterinary Office, FVO) and UK trade statistics were also used as available.

To complement insufficient information, and in line with the recommendation of the Commission of July 1998, “reasonable worst case assumptions” were used whenever extrapolation, interpolation or similar approaches were not possible.

A shortcoming in many dossiers, which had to be overcome by reasonable worst case assumptions, was insufficient information on compliance with the preventive measures put in place by the competent national authorities. For most countries
additional information on this issue could therefore improve the basis for the risk assessment further.

While for E.U. Member States reports from the missions of the FVO were generally available, this is not the case for Third Countries, with the exception of Switzerland. This is important because in case of conflicting information the FVO-mission reports were generally taken as the authoritative source. Mission reports have also been demonstrated to be very useful sources to fill gaps in the available information.

In addition the information base for third countries could also be improved by extensive exploitation of additional publicly available sources. Given these considerations it might be argued that the foundation on which the assessments for third countries are based is not in all cases fully equivalent to the one for the Member States.

Another problem with data availability was recognised, as some countries did not provide data before 1988. In view of the importance of this period for possible initial challenges and recycling of BSE, and in order to treat all countries equally the independent experts stated the following:

“Whenever the available information does not cover the period 1980 to 1988, an open question remains as to the challenge and stability of the system during that period. To this end the following was generally applied:

**Challenge:** Given the fact that the UK-epidemic was building up during that period, the implication is that any country that traded live cattle or MBM with the UK in this period could have imported some BSE-infectivity. If the system was unstable during that period (what was frequently the case) the potentially incoming BSE-infectivity could have been amplified.

In order to have a first approximation of the possible external challenge, UK-export data to the country in question were used. The Commission is also invited to provide the appropriate EUROSTAT data for the same purpose. An analysis of the different import/export figures from different sources would be most useful to improve the information basis for the period in question for all countries.

**Stability:** The stability of the system prior to 1988 is estimated on the basis of the available information, if necessary through extrapolation from the last known data.

If it is not possible to base an assessment of imports on the UK export data or to extrapolate the stability, it will be assumed that the country was subject to a low challenge while its BSE/cattle system was not fully stable. This unfavourable situation is assumed to have lasted until the available data allow assessing the situation differently”.

The impact of incoming cattle on the GBR of the receiving country is assessed on appraisal of the BSE situation in the exporting countries at time of export. Should it become apparent that this appraisal was wrong, the assessment of the
geographical BSE-risk of the receiving country would have to be reviewed. Imports from not-assessed Countries could not be taken into account. It was also in principle impossible to take account of triangular trade as a route for external challenges to develop.

2.5 Monitoring the Evolution of the Geographical BSE-Risk

In order to monitor the evolution of the GBR, it is very important to improve the ability to identify clinically and sub-clinically BSE-infected animals and potentially infected MBM.

According to field observations in Switzerland, the incidence of BSE is higher in fallen stock and in cows offered for emergency slaughter than in healthy looking animals presented at routine slaughter.

Since the GBR-assessment exercise started, three rapid post-mortem tests for BSE became available. These make appropriate intensive surveillance programmes possible, targeting at-risk sub-populations such as adult cattle in fallen stock or in emergency slaughter, cohorts of confirmed BSE cases. Results from such programmes, applied to statistically justified samples, could improve the basis for future assessments of the GBR, or help to verify the current risk assessment.

Three rapid tests in bovines have been shown by the European Commission (European Commission, 1999, The Evaluation of Tests for the Diagnosis of Transmissible Spongiform Encephalopathies in Bovines – see DG-SANCO internet site at [http://europa.eu.int/comm/dgs/health_consumer/index_en.htm](http://europa.eu.int/comm/dgs/health_consumer/index_en.htm)) to have excellent potential (high sensitivity and specificity) for detecting or confirming clinical BSE for diagnostic purposes or for screening dead or slaughtered animals, particularly casualty animals or carcasses to be used for rendering.

The above tests are:

- **Prionics**: an immuno-blotting test based on a western blotting procedure for the detection of the protease-resistant fragment PrP\textsuperscript{Res} using a monoclonal antibody
- **Enfer**: a chemiluminiscent ELISA, using a polyclonal anti-PrP antibody for detection
- **CEA**: a sandwich immunoassay for PrP\textsuperscript{Res} carried out following denaturation and concentration steps. Two monoclonal antibodies are used.

The currently available rapid post-mortem tests are able to prove the presence of PRPres in the CNS of cattle that are close to the end of the incubation period or already clinically ill. However, these tests cannot be considered to be able to identify pre-clinical cases at earlier stages of the incubation. The SSC, therefore, regards these tests to be useful for complementing existing surveillance efforts based on notification of BSE-suspects and detection of infected cattle with heavy loads of infectivity.

They should not, however, be used to guarantee the absence of the BSE-agent from an individual animal tested and found to be negative. The SSC wants to underline
its support for the development of improved rapid BSE-diagnostic tests ultimately aimed at having reliable ante-mortem tests able to detect pre-clinical BSE.

Moreover, for an accurate assessment of the future trends in GBR, compliance data (from farming/slaughtering/rendering industries) will be especially important. This information will be needed to determine the effectiveness of the various preventive measures, including bans, adopted and hence their impact on the GBR.

2.6 RELATION OF THE GBR TO THE OIE CODE ON BSE

2.61 The role of Risk Assessment

The OIE International Animal Health Code, Chapter 3.2.13 related to BSE, adopted May 2000, states that the status of a country or zone can only be determined from the outcome of a risk analysis. The OIE – International Animal Health Code, Section on Risk Analysis (section 1.4) outlines methods for this process as they are related to issues for the importation of animals or animal products. The OIE identifies the components of the risk analysis process as: hazard identification, risk assessment, risk management and risk communication. The risk assessment is the component of a risk analysis that estimates the risk associated with a hazard. Risk assessment methods should be chosen in relation to the specific situation. They may be qualitative or quantitative. The SSC method for the assessment of the Geographical BSE-Risk is one of the possible qualitative methods that can be used for the risk assessment component of this process. It is, however, an innovative approach using terminology different to those applied in the risk assessment literature and the OIE-section on risk analysis.

The SSC method for the assessment of the geographical BSE-risk is comparable to the OIE-guidance on risk analysis and in particular the chapter on risk assessment. The following points should be taken into consideration when determining the comparability of the SSC-method to other potentially proposed methods:

- The hazard identification is not included in the SSC-method for the assessment of the GBR as it was taken for granted that the BSE-agent is the hazard (see also the SSC-opinion on Human Exposure Risk).

- The release assessment required according to the OIE-guidance could be compared with the assessment of the “external challenge” and the “internal challenge” and their interaction as described in this opinion. The SSC assessment is not completed if the risk of an external challenge has been identified as negligible. This is contrary to the OIE-guidance. This SSC approach is justified by the high degree of uncertainty with the epidemiology and biology of the BSE-agent as well as with its monitoring and surveillance.

12As a follow-up to its earlier validation studies on appropriate heat treatments of animals meals, the Joint Research Centre has conducted a study on the Prevention of Epidemic Diseases by appropriate Sterilisation of Animal Waste. According to SSC Opinion (20-21 January 2000), the test may become, after further validation, a useful additional part of verification and control protocols for verifying the appropriateness of processing equipment in rendering plants (effective wet sterilisation carried out at least at 133°C/207/3 bars), provided a sample of appropriate test material is available to be processed.
The SSC method attempts to address the stability of the assessed BSE/cattle systems as a means to establish its capacity to resist future challenges that are currently unknown.

- One might, however, compare the thrust of the SSC-method with an exposure assessment. The assessment of the inherent stability of a given BSE/cattle system with regard to BSE might be compared, to a certain degree with an analysis of the pathways needed to allow the exposure of animals to BSE. In an unstable system the pathways are open and would lead to exposure whereas in a stable system the risk of exposure occurring is much lower because the pathways are closed. Typically, a pathway assessment would depend on the specific situation and could, according to the OIE, vary from country to country. The SSC-method applies systematically one model of the BSE/cattle system that describes the pathways in a fully transparent and standardised manner. This provides a basis for obtaining comparable results in different countries.

The SSC-method derives a similar end-point as an exposure assessment described in the OIE-guidelines for risk assessment: it provides a qualitative estimation of the likelihood of the exposure to an identified hazard (the BSE-agent), at a given point in time. However, the SSC-method requires assessing the consequences of past exposures, in the SSC-terminology the internal challenges, which together with the external challenges again interact with the stability and create a new exposure situation. Because of the importance of the time dimension in this delayed process the SSC-terminology seems to be more adequate to describe the positive feedback loop that is responsible for the BSE risk than the more static terms used in conventional Risk Analysis and Risk Assessment.

The SSC-risk assessment is well in keeping with the recommendation in the BSE-chapter of the OIE code. There it is requested to include all factors that could have lead to a risk of introducing or propagating the BSE agent in the country/region under consideration. This list is in fact very similar to the list of risk factors used by the SSC.

According to the BSE-chapter of the animal health code of the OIE, a BSE-risk analysis has to evaluate whether potentially infected material was imported, and, in such a case, whether the conditions in the country were/are sufficient to cope with potentially infected material, i.e. to prevent the disease being propagated. This is, indeed, exactly the objective of the SSC-method.

The OIE’s list of factors that should be taken into account when analysing the BSE-risk includes:

- importation of meat-and-bone meal (MBM) or greaves potentially contaminated with a transmissible spongiform encephalopathy (TSE) or feedstuffs containing either; (note: MBM-imports are a very important part of the external challenge which is assumed by the SSC to be the only initial source (except in the UK). Due to lack of data the SSC currently did not take account of greaves or feedstuff-imports);

- importation of animals, embryos or ova potentially infected with a TSE; (note: while animal imports are an essential element of the external challenge
assessment, the SSC does not take account of embryos or ova as the risk of transmitting the disease via these routes is regarded to be insignificant in comparison to the import of MBM and infected live cattle;

- consumption by cattle of MBM or greaves of ruminant origin; (note: the use of MBM is a central point of the SSC-assessment and greaves, and bone meal have been addressed whenever data were differentiated enough to allow for this);

- origin of animal waste, the parameters of the rendering processes and the methods of animal feed production; (note: this is one of the central points of the SSC-method, determining the stability of the system It is covered under the headings SRM-ban, rendering, and cross-contamination in the reports);

- epidemiological situation concerning all animal TSE in the country or zone; (note: the SSC does not take account of other animal TSEs because (a) the available data were very poor and (b) the link with BSE is not scientifically established, even for scrapie); and

- extent of knowledge of the population structure of cattle, sheep and goats in the country or zone. (note: while the information on the population structure – and dynamics- of the cattle population is taken account of, the information on small ruminants is, for the time being, not considered by the SSC).

The OIE also requests that the following measures, and their date of effective implementation (“relevant period of time”), be considered when determining the BSE-status. The SSC-method, however, considers them together with the other risk factors:

- compulsory notification and investigation of all cattle showing clinical signs compatible with BSE; (note: this factor is taken into account in the SSC-methodology when assessing the capacity of the system to identify clinical BSE-cases and to eliminate animals at risk of being infected before processing);

- a BSE surveillance and monitoring system with emphasis on risks identified; (note: also taken into account by the SSC when assessing the BSE-surveillance and when assessing the compliance with the feed and SRM bans);

- an on-going education programme for veterinarians, farmers, and workers involved in transportation, marketing and slaughter of cattle, so as to encourage reporting of all cases of neurological disease in adult cattle; (note: this is an integral part of the SSC-assessment of the surveillance system);

- examination in an approved laboratory of brain or other tissues collected within the framework of the aforementioned surveillance system; (note: again taken into account by the SSC in the context of the surveillance assessment);

- treatment of at-risk animals linked to confirmed cases (culling) (note: covered by the SSC as a separate point contributing to the ability of the system to identify clinical cases and to eliminate at risk animals).

From the above it is clear that there is a close similarity between the relevant factors identified by OIE and those being used by the SSC to assess the GBR.

The SSC provides a detailed methodology for assessing the geographical BSE-risk, taking account of all relevant factors, including those listed in the BSE-chapter of the International Animal Health Code of the OIE. The SSC method also involves an external review of the GBR on the basis of information provided by countries.
and, in view of the long incubation period of the disease and its initially probably slow progress, it tries to cover the last twenty years. As it is based on a prescribed model of the dynamics of the BSE-disease, this methodology can be applied consistently and transparently to available information. The application of the principle of reasonable worst case assumptions and special care to ensure consistency of these assumptions allows a reasonable estimation of the GBR even in cases where the available information is not fully satisfactory.

3. Implication of the GBR on Food and Feed Safety

From the definition of the GBR (see section 2.1) it is clear that it refers to the risk situation at the live-animal level.

At a given GBR the risk that food or feed is contaminated with the BSE-agent, depends on three main factors:
1. the likelihood that bovines infected with BSE are processed;
2. the amount and distribution of infectivity in BSE-infected cattle at slaughter;
3. the ways in which the various tissues that contain infectivity are used.

In addition the trading of potentially contaminated foods and feeds also influences this risk.

3.1 Likelihood that Bovines Infected with BSE are Processed

The likelihood that processed bovines are infected with BSE (processing risk) depends obviously on the GBR. However, the processing risk may differ for different cattle sub-populations, defined on the basis of criteria such as herd history, feeding history, date of birth in relation to identified challenges.

If the difference in processing risk of different sub-populations is known, excluding those that carry a higher specific processing risk would reduce the overall processing risk below the level that is indicated by the overall GBR.

This is for example possible by excluding birth cohorts born before an effective MBM-ban from slaughter. The exclusion of fallen-stock (in particular adult cattle) from rendering also reduces the processing risk. Ensuring that as many as possible of the infected (clinically and pre-clinically) cattle are excluded from processing also reduces the processing risk. The quality of the BSE-surveillance and the related measures (culling) are essential in this context.

---

25 See, for example the SSC opinion on “closed herds”, or on the “Date based export scheme” for criteria that are used to define sub-populations with a much lower BSE-risk.
26 The Date based export scheme, excluding animals born in the UK before the ultimate MBM ban of 01/8/1996 from export, is an example for the application of this principle.
3.2 AMOUNT AND DISTRIBUTION OF INFECTIVITY IN BSE ANIMALS

3.21 Amount

The amount of infectivity carried by an infected animal strongly depends on the incubation stage it is in. Assuming that most infection happen close to birth, the age of an animal is a good approximation of the potentially possible incubation stage and hence its infective load.

For instance, the infective load of animals below 24 months of age is in general very much lower than it would be possible for an animal of 60 months, assuming that both were infected shortly after birth.

Reducing the age at slaughter can hence reduce the infective load that potentially could enter the human food chain. Excluding older animals from rendering would have a similar effect on the feed chain.

The OTMS (Over Thirty Months Scheme) that excludes in the UK all animals older than 30 months from the human food and animal feed chain makes use of this effect. As, in the meantime, all animals that are allowed to be processed are also born after the latest MBM-ban (01/08/1996), it can be assumed that the combined effect of the OTMS and the feed-ban very effectively reduces the processing risk below the level expected from the current GBR (level IV).

3.22 Distribution

It is known that in an infected cattle that is approaching the end of the incubation period, the BSE infectivity is very unequally distributed. Certain tissues (the so-called SRM – Specified Risk Material) represent a particularly high risk. Their exclusion from further use (food or feed) reduces the infective load that could enter the respective chains. (See also the opinion of the SSC on SRM of Dec. 1997).

3.3 USE OF THE VARIOUS ORGANS AND TISSUES FROM BSE-ANIMALS

Each tissue/organ of a bovine can be used for a range of uses. Some of them require processing that is known to be capable to reduce BSE-infectivity.

The SSC has expressed its opinion on the production of gelatine, tallow, MBM, and a range of other bovine based products that may be used for food, feed or non-food/feed purposes. It has defined the conditions that have to be met to achieve maximal BSE-infectivity reduction and/or the BSE-infectivity reduction that can be expected from the normally applied/applicable processes. It has also included into these conditions considerations of the BSE-risk carried by the raw material with regard to tissues and the geographical origin of the animals.
With regard to process conditions it has been shown that some reduce BSE-infectivity\(^{27}\), others (e.g. normal cooking, sub-standard rendering) have no measurable impact on it.

### 4. Conclusion

The assessment clearly shows that the current GBRs reflect, more than anything else, differences among the commercial and agricultural practices existing between the early 80s and the early 90s, a time when knowledge on BSE, and its public health impact, was very limited. Since then, however, the awareness has tremendously increased and effective measures have been put in place to minimise the impact of BSE on public health.

In fact, at a given GBR, the risk of humans or animals to be exposed to the BSE-agent can be influenced by measures

- before slaughter, that exclude at-risk animals (such as fallen-stock\(^{28}\)) and/or reduce their age at processing;
- during slaughter by excluding SRM from further processing,
- after slaughter by applying appropriate processes, able to reduce BSE-infectivity.

These measures might also be modulated in view of the intended end use of the meat or other bovine derived products. If control can be ensured, products that are only used for non-food/non-feed uses (also called industrial uses) could carry a higher risk than food or feed products. The SSC has the intention to address this issue in more detail in a specific opinion.

PART II

REPORT ON THE ASSESSMENT OF THE

GEOGRAPHICAL BSE RISK OF

SPAIN
EXECUTIVE SUMMARY

OVERALL ASSESSMENT

The current geographical BSE Risk (GBR) level is III, i.e. it is likely that cattle are infected (pre-clinically or clinically) with the BSE-agent but it is not confirmed.

The current surveillance system is passive, i.e. depending on notification of suspects, and because of the intrinsic limitations of such systems not able to detect all clinical BSE cases. It is possible that BSE will be confirmed in Spain within the next years, in particular if active surveillance targeted on risk populations would enhance the performance of the surveillance system.

Stability: Before 1994 the Spanish BSE/cattle system was extremely/very unstable. MBM could legally be fed to cattle, even if this was not commonly the case, rendering was unable to reduce incoming BSE-infectivity significantly, and SRM and fallen stock were rendered, also from imported animals. The 1994 feed ban improved the stability to “unstable”. The 1996 SRM ban for animals imported from BSE-affected countries, together with improved surveillance (since end 96) and better rendering (since 1997) made the system “neutrally” stable in 1997. With further improved surveillance (1997), rendering (mid 1998) and feed-controls (1999), the system became stable in mid 1998/99; i.e. circulating or incoming BSE-infectivity will be reduced over time.

External challenge: Between 1980 and 89 nearly 4,000 cattle were imported from the UK, 943 Friesian for breeding and the rest beef cattle for fattening and slaughter at young age. Of the 943 breeding-cattle, 161 were born after 1/1/85, the year when the case incidence of that birth cohort in the UK surpassed 8,000 BSE cases. Of these 161 animals, 56 are seen to be critical because they probably were pre-maturely killed at an age of 4 to 6 years, i.e. an age when they would just be approaching the end of a normal incubation period, if they were infected with BSE before export. These imports posed a high external challenge. Between 1985-1997, more than 350,000 beef cattle were imported from other European countries now known to be affected by BSE, according to the Spanish authorities exclusively for fattening in specialised installations and slaughter at young age. The import of 14,551 cattle from Portugal mostly consisted of fighting bulls that are assumed to be less at risk due to their special upbringing. The imports from BSE-affected countries other than the UK are assumed to have added to the external challenge to some extent until 1996, when the SRM-ban for imported cattle made the effect of this challenge negligible.

Interaction of stability and challenge: An extremely or very unstable system was exposed to significant challenges over a long period of time but particularly during 1989-1993 when the critical UK-imports were pre-maturely killed. It is hence likely that the BSE-agent entered the system and was recycled and, over time, amplified. As the system is only stable since mid-1998/99, it is expected that BSE is currently present in the domestic cattle population, at levels below the detection limits of the BSE surveillance system in place.
Assuming that measures in place continue to be appropriately implemented and no new external challenge occurs, the probability that cattle are (pre-clinically or clinically) infected with the BSE-agent will decrease over time.

Additional efforts to ascertain clinical and pre-clinical BSE-cases and remove them, and other animals at risk of being infected by BSE, from processing will assist in reducing the GBR.

Improved surveillance, including large scale active screening of at-risk sub-populations of asymptomatic animals, and continuing good implementation and control of the current measures, would support the decrease of the GBR. It would in any case make a re-assessment possible as soon as sufficient new data are generated.

**JUSTIFICATION**

1. **AVAILABLE DATA.**

   The information available was sufficient to complete the assessment

2. **STABILITY**

   2.1 **Ability to identify BSE-cases and to eliminate animals at risk of being infected before they are processed.**

   - Until today the Spanish surveillance system is relying on notification of suspects and it is therefore not able to guarantee identification of small numbers of clinical BSE-cases, should they occur. Hence the ability to exclude infected cattle or animals at risk to be infected from processing is low.
   - Should a case be detected, the cattle identification and monitoring system would allow back-tracing it. This enhances the capacity to exclude related animals at risk of being infected from processing.

   2.2 **Ability to avoid recycling of BSE-infectivity, should it enter processing**

   - Until 1997 the system was probably not able to avoid recycling of the BSE-agent. Should BSE have been present in live animals, nearly all of it would have been rendered because SRM and fallen stock were processed and used for feed. As rendering was probably not able to significantly reduce BSE-infectivity, most of the introduced BSE-agent would have survived the process and appeared in the produced MBM. Even with the small risk that some of this MBM could have reached domestic cattle, recycling of the agent would probably have taken place.
   - The 1994 MMBM-ban reduced the likelihood that (contaminated) MMBM reached cattle and improved the ability to avoid recycling of the BSE-agent.
   - Since 1996 the SRM and fallen stock of animals imported from countries now known to have BSE are excluded from processing. This reduced the risk of introducing the agent from outside (external challenge). It had no effect on the potential to recycle domestic BSE-infectivity, should it exist.
Since 1998 all rendering is according to standard and since then the ability to avoid recycling of (domestic and imported) BSE-infectivity can be regarded as good.
It is therefore concluded that the ability of the Spanish BSE/cattle system to avoid recycling of the BSE-agent, should it have been introduced into the country, was very poor up to 1994 and is good since 1998/99.

2.3 Overall assessment of the stability

Until 1994, the Spanish BSE/cattle system was been extremely unstable or very unstable. Feeding MBM to cattle was infrequent but possible, the rendering system was not sufficient with regard to BSE inactivation, and no SRM ban was in place. Incoming BSE-infectivity would probably have been (partly) recycled and rather quickly amplified.

Between 1994 and 1997 the stability of the system was improved to “unstable”, with
- the introduction of an MMBM-ban in 1994, (cross contamination reduced the efficiency of the ban in the first years);
- the removal of SRMs in imported cattle since 1996 (it reduced the risk that BSE could have entered the feed chain from outside); and
- improvements in the rendering system since 1996 which significantly increased the potential of that processing step to reduce BSE-infectivity.

Since mid-1998/99 the system is stable, due to the further improved rendering combined with better feed controls and increased efforts to reduce cross-contamination. The improvements in the surveillance since 1997 support this assessment.

3. CHALLENGES

The imports from UK fall into two categories: 943 breeding cattle (Friesian) and 3,021 cattle for fattening. The latter were processed before an age of 24 month in the Canary-Islands.

Of the 943 breeding-cattle, 161 were born in the UK after 01/01/1985 (when the case incidence in that UK-birth cohort surpassed 8,000 animals) and before end 1987. While the breeding cattle normally reached ages of 10 and more years, 56 of these 161 cattle (35%) died at an age between >4 and <=6 years. In comparison to the normal Spanish rate of casualties in this type of animals (about 18%) this is a high fraction. These 56 animals were imported in 1987/88/89 and probably rendered between 1989 and 1993, while the system was still at least very unstable. As it is assumed that older animals would have become clinical if infected before export, and younger animals would not have carried high infectivity-loads when killed, this critical contingent of 56 animals is seen as a high challenge.

More than 350,000 cattle were imported between 1985-97 from other European countries known to have BSE. According to the Spanish authorities exclusively for fattening and slaughter at young age.
These imports are seen to have posed an additional but much smaller external challenge that became negligible with the exclusion of SRM of the imported animals from the feed chain in 1996.

According to the Spanish authorities, the UK consignment of 1,200 tons MBM that is indicated in the Spanish import statistics for 1988 did not enter the country because it was completely re-exported to other EU-member States, namely The Netherlands. The imports of MBM would therefore only have represented a negligible challenge. As long as it cannot be proven beyond doubt that the exported MBM was identical with the UK-imports, a reasonable worst case assumption would be that some of the imported MBM remained in Spain, leading to a very low or low external challenge.

In consequence of the interaction of a high external challenge with an at least very unstable system a certain internal challenge is likely to have been built-up, keeping the overall challenge at a high level after the end of the external challenges.

4. CONCLUSION ON THE RESULTING RISKS

4.1 Interaction of Stability and Challenge

Prior to 1994 an extremely unstable BSE/cattle system had to face significant external challenges, due to imports of potentially BSE-infected animals.

This makes it likely that BSE reached the domestic cattle population and created an increasing internal challenge since the late 1980’s leading to a high overall challenge even after the main external challenge faded away in 1993.

The ability of the system to cope with incoming or circulating BSE-infectivity gradually improved (SRM ban on imported animals (1996), better rendering (after 1997).) It reached an “unstable” level in 1994 (MBM-ban). This meant that BSE-infectivity already present in the system would still have been recycled and slowly amplified. Therefore the overall challenge remained high, even after the main external challenges ceased. Only since mid 1998, when the system became stable the overall challenge starts to decrease – as long as no new external challenges occur.

A reasonable worst case assumption is therefore that the combined challenges to the system have reached a high level in 1994 and remained high until 1998 when it slowly started to decrease.

4.2 Risk that BSE infectivity enters processing

The risk that imported infected cattle were processed was highest when the breeding cattle imported from the UK (1980-89) were slaughtered, in particular when animals from the birth years 85-87 where culled prior to their normal age of slaughter, i.e. at an age between 4 and 7 years in the period 1989-1993. The fattening cattle imported between 1985-97 from other European countries known to have BSE increased this risk. If single animals of these latter imports survived long enough to become infective, they would reach slaughter between 1990 and 2002/3.

The second source of this risk is processing of infected domestic cattle. Albeit it has not been confirmed, it is likely that some domestic cattle were infected
since the late 80s or early 90s. Hence an additional, “internal” component of the processing risk started to grow one incubation period later, i.e. 1993/95.

- It is concluded that there is a significant risk that BSE infectivity entered processing since the mid-80s. It remained at a constant level until today, the decline of the import-related component being counterbalanced by the increase of the domestic component of the risk.

4.3 Risk that BSE infectivity is recycled and propagated

- Until 1994 the extremely/very unstable system would have recycled and propagated the agent, should it have been introduced. The risk that this happened is directly proportional to the external challenge – which is considered to be high until at least 1998.
- The introduced BSE infectivity could have exposed native cattle. Thus BSE-infectivity could have started to circulate in the system around the early 90s, got recycled and amplified and the disease could have been propagated.
- The resulting propagation risk reached very high levels in the early 90s and remained at this level until 1998.
- The risk that incoming infectivity was recycled and propagated was significantly reduced in 1996 when the SRM ban on imports was introduced.
- The improvement in the rendering system, which has been achieved in mid-1998, has reduced the risk of recycling and propagating and prevents further amplification.

5. CONCLUSION ON THE GEOGRAPHICAL BSE-RISK

5.1 The current GBR

The current geographical BSE-risk (GBR) level is III, i.e. it is likely that domestic cattle are infected with the BSE-agent but it is not confirmed.

The current surveillance system is passive, i.e. depending on notification of suspects, and because of the intrinsic limitations of such systems not able to detect all clinical BSE cases. It is possible that BSE will be confirmed in Spain within the next years, in particular if active surveillance would enhance the performance of the surveillance system.

5.2 The expected development of the GBR

- If improved surveillance, including large-scale active screening of at-risk sub-populations of asymptomatic animals, does not find BSE-cases and the current measures continue to be well implemented, Spain could be seen to move into GBR level II.
- As long as the system remains stable, the anticipated circulating BSE will continue to be slowly eliminated from the system and the GBR will, over time, decrease.

5.3 Recommendations for influencing the future GBR

- Excluding domestic SRMs (as foreseen in 2000/418/EC) and fallen stock from rendering will enhance the stability and speed-up the elimination of any BSE-risk from the country.
- Expanding the surveillance system to target high-risk populations such as adult cattle in fallen dairy stock and adult cattle presented for emergency slaughter
will improve the ability to identify and exclude from processing clinical and (some) pre-clinical BSE cases and hence increase the stability further. It would make detection of single cases of BSE more likely.

FULL REPORT

1. AVAILABLE DATA

1.1 Consistency, completeness and treatment of gaps in the available data

The information provided in the dossier and by additional sources was largely complete and consistent. Extrapolation, interpolation and realistic worst case assumptions were used to bridge gaps that could not be closed otherwise.

1.2 Sources of information used

- Information provided by the Country Authorities and the Country Expert
- FVO mission reports October 1996 and September/October 1998

1.3 Recommendations for improving the basis for assessing the GBR

The following information would improve the basis for assessing the GBR:

- Additional information on compliance with the implemented risk management measures, especially with regard to cross contamination and rendering.
- Details on MBM-imports prior to 1988.
- Results from a targeted surveillance, targeting asymptomatic cattle in high-risk populations such as adult fallen dairy stock and adult cattle presented for emergency slaughter.

1.4 Overall assessment of the suitability of the available information for the assessment

The information available was sufficient to complete the assessment.

2. STABILITY

2.1 Ability to identify BSE-cases and to eliminate animals at risk of being infected before they are processed.

2.11 Factor 1: Population data

2.111 Total size of the cattle herd; relative share of dairy, beef and dual use cattle

- In 1997 the total cattle population in Spain was approximately 5.8 million, which was an increase by over a million since 1980.
- There has been a shift in the ratio of dairy to beef cattle: In 1980 there was almost an equal amount of each (1 to 1). In 1997 beef cattle outnumbered dairy cattle by approximately 3 to 1. In absolute numbers there was a thirty-percent drop in the dairy population over a ten-year period.

2.112 Age distribution of cattle, alive and at slaughter

- The shift from dairy to beef cattle has lead to a lower average age of the total population and a decreased average age at slaughter.
For dairy cattle the average age at slaughter is between 7-8 years (according to the country expert).
Breeding cattle reach even higher age.

2.113 **Husbandry systems**
- Dairy cattle are farmed in an intensive manner, mainly (about 70-75%) in the northern part of Spain. The average holding size is small with 9-10 cows per farm. Average annual milk production was around 3,300 kg milk per year per cow during the eighties, 4,300 kg in 1990 and 4,700 kg in 1995.
- There is an overlap of dairy and hog farms in some parts of Aragon but co-farming (raising of cattle and pigs and/or poultry on the same farm in the same period of time) is, according to the Spanish authorities, not existing.

2.114 **Cattle identification and monitoring system**
- Since 25 November 1978 it is compulsory to individually identify cattle. At that time a national system was built-up and nation-wide eradication programs started (Tuberculosis, Brucellosis, Leukosis and Bovine Pleuropneumonia).
- The system was improved in 1997 when a computerised database was set up to assist with tracing the animals, and animals had to be tagged with two eartags. In addition all animals in transport must be accompanies by a health document.

2.12 **Factor 6 Surveillance**

2.121 **Description of the surveillance system and its development overtime**
- As an exotic disease, BSE was compulsory notifiable since long. It became specifically notifiable in 1990. However, awareness-raising measures started in 1989. A first information on BSE, including a description of its symptoms, was made available to the regional authorities around that time (before 1991). At the same time the BSE-video produced by MAFF-UK was translated into Spanish and distributed.
- In the context of the various eradication programmes for Brucellosis, Tuberculosis, Leukosis, etc. each farm is regularly visited by official veterinarians, normally twice or more per year. The Spanish authorities claim that at this occasion cattle showing clinical signs of BSE would have been recognised.
- Since 1952 compensation is paid for all animals slaughtered by official order. A ministerial order of 1955 states that normally 100% of the market value is provided. Exceptions are the eradication programmes for Tuberculosis etc. where only up to 80% of the market value is paid.
- No legal definition of BSE-suspicion was available in 1996, even if symptoms etc were already described in the leaflet mentioned above that was distributed in 1989/90. Since March 1996 a legal definition of a BSE-suspect exists in the instructions for prevention and surveillance on TSEs, prepared by the central authority. Animals with nervous symptomatology were not compulsorily tested (source: Mission report, 1996).
- Before 1996 the number of bovine brains examined annually was significantly less than what is recommended by the OIE. Between 1990-95, only 49 bovine brains were examined.
- In 1996/97 the surveillance of neurological diseases in cattle improved as in this period 158 samples were examined. Given an adult cattle population (Dec.1995) of 3.1 million the OIE requirement would have been to test >200 brains of cattle showing clinical signs compatible with BSE.
Surveillance improved significantly in 1998 with 1,026 samples being examined. However, only a small part of them were cattle with neurological symptoms or progressing diseases but, according to the country authority the requirements of 97/272 (similar to OIE-requirements) are fulfilled.

The system in Spain involves a number of regional laboratories that screen neurological cases by histopathology. Only if the findings are suggestive or inconclusive they are to be forwarded to the national reference laboratory for supplemental tests.

2.122 Quality of the surveillance system with regard to BSE

- The Spanish BSE-surveillance system is passive, depending on notification of BSE-suspects.
- Before 1996 the number of cattle brains tested for BSE was very low and the likelihood that BSE-cases could have been seen was low. The number of examinations of cases of neurological and progressive disease from cattle > 24 months increased since 1996 and meets minimum requirements of the OIE guidelines since 1998. This improved the ability of the surveillance system to recognise clinical BSE. Its performance remains depending of the notification of suspects. The number of suspects is still rather low.

2.13 Factor 8 (Culling)

- In 1996, Spain developed a response plan in the event of a confirmation of BSE.
- This plan would include the culling of the infected herd.
- As no case has been identified, it has not been implemented.

2.14 Overall appreciation of the ability to identify BSE-cases and to eliminate animals at risk of being infected before they are processed

- Until today the Spanish surveillance system is relying on notification of suspects and remains fully passive. Even if the regular visits of official veterinarians to all cattle farms are seen to be a positive point, they can, however, not guarantee that cattle with, often unspecific, BSE-compatible symptoms would be recognised.
- It is therefore not able to guarantee identification of small numbers of clinical BSE-cases, should they occur and hence the ability to exclude infected cattle or animals at risk to be infected from processing is low.
- Should a case be detected, the improved cattle identification and monitoring system would allow back-tracing it to its natal herd and the herds it had been raised. This enhances the capacity to exclude related animals at risk of being infected from processing.

2.2 Ability to avoid recycling BSE-infectivity, should it enter processing

2.21 Factors 3 and 4: Domestic MBM production and use

2.211 Domestic production of MBM
The average annual production of MBM is between 240,000 – 310,000 tons.

2.212 Description and history of Feed ban(s) and their compliance
- The first feed ban enacted in Spain (1994) was the mammalian to ruminant ban based on EU decision 94/381.
In July 1996 bovine protein and tissues originating from France, Ireland, Portugal, Switzerland and the UK were prohibited from the inclusion in ruminant feed.

2.213 Use of MBM (before and after feed ban(s))

According to the Spanish authorities, MBM was historically not used in cattle rations to any great extent. If it was used it was included with up-to 3% into calf-starters for calves destined for fattening, but not for dairy calves. The reason for this were on the one hand economic, i.e. the availability of soya at a competitive price: Spain had an import agreement with the United States which allowed the purchase of soya at low prices. Data comparing the price of soya and MBM, provided by the Spanish Authorities, show that there have been periods (i.e. July - October 88; October 92 - October 93 and first part 1996) where the price of soya was higher than that for MBM. However, over the period June 1988 - April 1996 the price of soya has been generally lower. According to the Spanish authorities these short-term fluctuations of the market were not be exploited by the Spanish feed-industry because of existing long term contracts and the technical problems of including another ingredient. On the other hand the reluctance of the cattle owners and the (perceived) problems of the feed-producers to guarantee the necessary hygienic standard of their produce also explain the low level of utilisation of MBM for cattle feed.

With the enactment of the 1994 MBM ban the likelihood of cattle being voluntarily exposed to MBM was further reduced, this is supported by the results of feed sampling in 1998/99.

However, cross-contamination was possible, at least until 1998, when feed control measures were enhanced. This reduced the efficiency of the feed ban and until 1998 dairy cattle/calves could have been exposed, involuntarily, to MBM.

2.22 Risk factor 5: SRM ban and treatment of SRM

2.221 Description and history of the SRM ban

There is no SRM ban in place for domestic cattle.

An SRM-ban for cattle, sheep and goats, imported from BSE-affected countries, was introduced in 1996, requesting disposal of brain, spinal cord, eyes, thymus, tonsil, spleen and intestines of these animals.

No compliance data are available. However, according to a declaration of the authorities, it is well implemented.

2.222 Fate of SRMS

SRM of imported animals are disposed of appropriately.

Domestic SRMs are rendered together with “normal” materials.

2.23 Risk factor 7: Rendering and feed production

2.231 Raw material used for rendering

Low and high-risk material from different species is rendered together, including fallen stock and domestic SRM. Note: The Spanish authorities mentioned that fallen stock is and was since long rendered in a limited number of plants that have separate lines for this material. In the same lines the SRM from imported animals are processed. The use made of the MBM produced from fallen stock was not clear while the MBM made from SRM is burned, in cement plants.
SRMs from cattle imported from countries with native BSE are excluded (since 1996). Cattle from these countries, which arrive dead in Spain, are treated as SRM.

In 1996 1,199,903 tons of raw material were rendered into 281,000 tons of MBM. The raw material sources were: 699,720 tons pigs (58%), 112,608 tons bovine (9%), 282,190 poultry/rabbits (24%), and 105,385 tons other (9%).

2.232 Rendering processes
- The 1996 report on the EU-veterinary inspection mission stated that the majority of rendering systems would be ineffective for inactivation of the BSE agent.
- The implementation of the July 1996 EU-Decision, mandating an overall change in the rendering system to 133°C, 3bar & 20 min., was not ensured before 1997, in some cases until spring 1998.
- Improperly processed MBM was produced and sold, at national level, to the feed industry up until the end of 1997-spring 1998. (FVO Inspection Report – Oct. 10, 1998).

2.233 Capacity of the rendering system to reduce any potential BSE-infectivity in the raw material
- Before 1996 most, and until 1998 some Spanish rendering plants were not able to considerably reduce BSE-infectivity, should it have entered the process.
- Since 1997 rendering improved but deficiencies were reported still in 1998.
- The current situation of the rendering industry is reported by the Spanish Authority to be conforming to the required standards (133/20/3) in all high- and all low-risk plants.
- A reasonable worst case assumption is therefore that before 1998 the Spanish rendering was incapable of significantly reducing BSE-infectivity and that the optimal degree of BSE-infectivity reduction was reached in mid-1998.

2.24 Cross contamination

2.241 Possible types of cross contamination
- Rendering: “Cross-contamination” of “normal” raw material with “high-risk” material, namely with domestic SRM and domestic fallen stock is generally the case. There is no confirmed information on separate rendering lines for different raw materials other than for (imported) SRM and hence a joint rendering is assumed.

- Feed-mills: Cross-contamination is possible because wherever cattle feed is prepared using the same lines as for pig feed. However, the fraction of the rendering industry that produces ruminant and non-ruminant feed in the same plants (not necessarily the same lines) and uses MBM for the latter was always small and is decreasing. The trend, however, is towards a complete separation of ruminant feed production from the production of MBM-containing non-ruminant feed.

- Transport and storage: Cross-contamination of cattle feed with (ruminant derived) MBM is possible during transport and storage of MBM as such and of feed stuffs designated for different species. The fact that in Spain MBM is handled in sacks or large bags reduces this risk to some extent.
On-farm: MBM is still included in feed preparations for pig and poultry. Therefore co-farming of pigs and cows would present a risk of on-farm cross-contamination. According to the Spanish authorities this risk is negligible because co-farming of cattle and pig and/or poultry is non-existing in Spain.

2.242 Measures undertaken to control cross-contamination

The Spanish authorities and the Spanish feed industry made significant efforts to correct and improve the system. In plants producing feed for non-ruminants and ruminants and using MBM for the former measures like flushing batches and special entry points for the MBM into the mill are taken to reduce in-mill cross-contamination.

However, the FVO Report of October 1998 found some non-compliance regarding the labelling of MBM sacks and the frequency of the self-controls carried out by the industry.

2.243 Assessment of the potential level of cross-contamination

The high number of plants producing compound feed stuffs (476) and numerous plants producing mammalian MBM (54) makes it difficult to assess the current situation with regard to cross-contamination of cattle feed with (potentially infectious) MBM.

Figures provided in June 2000 show that only a small fraction of the entire feed production comes from plants where ruminant feed could get in contact with MBM. However, in 1980-85 about 1.5 million tons of feed have been annually produced in those mills, between 1986 and 1990 about 1.16 million tons p.a., from 1991 to 1995 about 600,000 tons and in 1996-1999 still about 330,000 tons per year. It is not clear from the data how much of this production is ruminant (cattle) feed but in absolute terms the potential amount remains significant.

In the period 94-97, feed 705 samples of MBM-free cattle feed have been tested and no samples were found positive for MMBM, the detection limit being 0.3%. Figures for 1998 and 1999 where not available.

Since 1998 the labelling requirements for feedstuffs are generally implemented. However, some non-compliance regarding the labelling of MMBM sacks was observed by the FVO in Oct. 98.

The risk of cattle feed to be accidental contaminated with low levels of MMBM that, until 1998, could have been inappropriately produced, was never very high but also not negligible.

2.25 Overall appreciation of the ability to avoid recycling BSE-infectivity should it enter processing

Until 1994 the system was probably not able to avoid recycling of the BSE-agent. Should BSE have been present in live animals, nearly all of it would have been rendered because SRM and fallen stock were processed and used for feed. As rendering was probably not able to significantly reduce BSE-infectivity most of the introduced BSE-agent would have survived the process and appear in the produced MBM. Even with the (small) risk that some of this MBM could have reached domestic cattle, recycling of the agent would have taken place.

The 1994 MMBM-ban reduced the probability that (contaminated) MMBM reached cattle and improved the ability to avoid recycling of the BSE-agent.
Since 1996 the SRM and fallen stock from animals imported from countries now known to have BSE are excluded from processing. This reduced the risk of introducing the agent from outside (external challenge). It had no effect on the potential to recycle domestic BSE-infectivity, should it exist.

Since 1998 all rendering is according to standard and since then the ability to avoid recycling of (domestic) BSE-infectivity can be regarded as good.

It is therefore concluded that the ability of the Spanish BSE/cattle system to avoid recycling of the BSE-agent, should it have been introduced into the country, was very poor up to 1994 and is good since 1998/99.

2.3 Overall assessment of the stability

Until 1994, the Spanish BSE/cattle system was extremely unstable or very unstable. Feeding MBM to cattle was infrequent but possible, the rendering system was not sufficient with regard to BSE inactivation, and no SRM ban was in place. Incoming BSE-infectivity would probably have been (partly) recycled and rather quickly amplified.

Between 1994 and 1997 the stability of the system was improved to “unstable”, with
- the introduction of an MMBM-ban in 1994, (cross contamination reduced the efficiency of the ban in the first years);
- the removal of SRMs in imported cattle since 1996 (it reduced the risk that BSE could have entered the feed chain from outside); and
- improvements in the rendering system since 1996 which significantly increased the potential of that processing step to reduce BSE-infectivity.

Since mid-1998/99 the system is stable, due to the further improved rendering combined with better feed controls and increased efforts to reduce cross-contamination. The improvements in the surveillance since 1997 support this assessment.

3. CHALLENGE

3.1 External Challenge

3.11 Factor 2: Import of live cattle

Between 1980-89 Spain imported 3,964 cattle from the UK. Imports from UK ceased after 1989. Of the 3,964 cattle imported 610 were imported from the UK during the period of highest risk (1988-89).

The imports from UK fall into two categories: 943 breeding cattle (Friesian) and 3,021 cattle for fattening. The latter were processed before an age of 24 months in the Canary-Islands.

Of the 943 breeding-cattle, 161 were born in the UK after 01/01/1985 (the case incidence in that UK-birth cohort surpassed 8,000 animals) and before end 1987. While the breeding cattle normally reached ages of 10 and more years, 56 of these 161 cattle (35%) died at an age of 4 to 6 years. In comparison to the normal rate of casualties in this type of animals (about 18%) this is a high fraction. Normal reasons for premature killing of imported breeding animals were quoted as insufficient productivity (6%), sterility (4%), mastitis (3%), birth related problems (2%), ketosis (2%), sanitary campaigns (1%).
These 56 animals were imported in 1987/88/89 and were rendered between 1989 and 1993, while the system was still very unstable. If it is assumed that older animals would have become clinical if infected before export, and younger animals would not have carried high infectivity-loads when killed, this critical contingent of 56 animals would have to be seen as a high challenge.

More than 350,000 cattle were imported between 1985-97 from other European countries known to have BSE, mostly for slaughter at an age that would not allow carrying substantial amounts of infectivity. The countries of origin included France, the Netherlands, Belgium, Ireland, Switzerland and Portugal.

According to the country expert, the 14,551 bovines from Portugal were fighting bulls. To date, BSE has not been diagnosed in fighting bulls in Portugal who are assumed to be less at risk due to their special upbringing.

It was explained by the Spanish authorities that the fattening of the imported cattle happens in land-less enterprises in the north-east of Spain, while the dairy industry is mainly in the North-East and the extensive beef production in the southern parts of Spain.

It was further explained that the imported breeds are not normally used for dairy (or extensive beef) production in Spain. It is therefore regarded highly unlikely that illegally cattle imported for fattening did enter the national herd. However, no confirmation of controls of the proper use of the imported cattle was provided and singular cases of wrongdoing can therefore not be excluded.

The significant imports of cattle for fattening from other countries with BSE are therefore seen to have posed an additional but much smaller external challenge.

The effect of this challenge became negligible with the exclusion of SRM of the imported animals from the feed chain in 1996.

3.12 Factor 3: Import of MBM or feed containing MBM

The available statistics (only after 1988) indicated that importation of MBM was a small percentage of the total MBM produced in Spain. In 1988 a consignment of 1.021 tons was apparently imported from the UK. However, the Spanish authorities verified this and provided evidence that this material was imported by an import/export company and directly transferred via lorry to other EU Member States or via boat to the Netherlands. A final confirmation is ongoing.

Table 1: Import of Meals or pellets not fit for human consumption made from Meat, Offal, Fish or Shellfish, Mussels or other aquatic Invertebrate. No information is available on the detailed composition of the registered imports. As a realistic worst case assumption it seems to be justified to assume that at least part of the imports were MBM. Data before 1988 were not available. [unit: metric tons, rounded]
• Of the other recorded imports a part originated from countries known to have BSE, however, these imports carried a smaller risk. In addition it has to be taken into account that the information on animal proteins traded towards and from Spain does not differentiate between the type of animal proteins.

• The Spanish authorities traced the UK consignment of 1988 down to one import/export company, which apparently re-exported the UK-material in two consignments to neighbouring EU-Member States and, by boat, to the Netherlands. However, the exports were slightly higher than the imports, making manipulation of the material in Spain likely. A reasonable worst case assumption is therefore that some of the UK material remained in Spain, entered the Spanish feed cycle, and represented a very low to low challenge.

### 3.2 Internal challenge

#### 3.21 Interaction of external challenge and stability, potentially leading to domestic prevalence

• An extremely or at least very unstable system was exposed to a high external challenge, mainly resulting from cattle imported in 1987/88/89 from the UK and killed between 1987 and 1993 at an unusual young age but old enough to carry significant infective loads if infected prior to export from UK. The import of live cattle for fattening from other BSE-affected countries did add to this challenge, as could have done the MBM imports.

• If the BSE-agent was indeed imported, the extremely or very unstable system would have lead to exposure of domestic cattle and their subsequent infection.

#### 3.22 Domestic prevalence

• It is regarded to be likely that the BSE agent was imported into Spain, was recycled and amplified, resulting in a small domestic prevalence.

• Given the unstable system, circulating and incoming BSE-infectivity could have been recycled and amplified until 1998, leading to an increasing domestic prevalence presenting an increasing internal challenge to the system.

• It is assumed that the internal challenge continued to rise even after the external challenge decreased after 1993.

• In the light of the intrinsic limitations of a passive surveillance system, the current zero-incidence of clinical cases in domestic cattle cannot be taken as a guarantee that BSE is absent from the Spanish cattle population.

### 3.3 Overall assessment of the combined challenges

• During the period 1987-1993 the 87/88/89-imports of live cattle from UK posed a high external challenge to the system. It cannot be excluded that some MBM-imports added to this external challenge as did the imports from other BSE-affected countries that also kept the external challenge at a non-negligible level until 1996.

• In combination with the assumed internal challenge that could have developed due to the amplification of incoming BSE-infectivity by the extremely/very unstable and unstable system, the overall challenge was at high levels in the early 1990's, and remained there until 1998. Since then it is decreasing.
4. CONCLUSION ON THE RESULTING RISKS

4.1 Interaction of Stability and Challenge

- Prior to 1994 an extremely unstable BSE/cattle system had to face significant external challenges, due to imports of potentially BSE-infected animals.
- This makes it likely that BSE reached the domestic cattle population and created an increasing internal challenge since the late 1980’s leading to a high overall challenge even after the main external challenge faded away in 1993.

Figure 1: Development of stability and challenge over time

- The ability of the system to cope with incoming or circulating BSE-infectivity gradually improved. (SRM ban on imported animals (1996), better rendering (after 1997).) It reached an “unstable” level in 1994 (MBM-ban). This meant that BSE-infectivity that was already present in the system would still be recycled and slowly amplified. Therefore the overall challenge remained high, even after the main external challenges ceased. Only since mid 1998, when the system became stable the overall challenge starts to decrease – as long as no new external challenges occur.
- A reasonable worst case assumption is therefore that the combined challenges to the system have reached a high level in 1994 and remained high until 1998 when it slowly started to decrease.

4.2 Risk that BSE infectivity enters processing

- The risk that imported infected cattle were processed was highest when the breeding cattle imported from the UK (1980-89) were slaughtered, in particular when animals from the birth years 85-87 where culled prior to their normal age of slaughter, i.e. at an age between 4 and 7 years, i.e. 1989-1993. The fattening cattle imported between 1985-97 from other European countries known to have BSE increased this risk to some extent. If single animals of these latter imports survived long enough to become infective, they would reach slaughter between 1990 and 2002/3.
- The second source of this risk is processing infected domestic cattle. Albeit it has not been confirmed, it is regarded to be likely that some domestic cattle were infected since the late 80s or early 90s. Hence an additional, “internal”
component of the processing risk started to grow one incubation period later, i.e. 1993/95.

- It is concluded that there is a significant risk that BSE infectivity entered processing since the mid-80s. It remained at a constant level until today, the decline of the import-related component being counterbalanced by the increase of the domestic component of the risk.

4.3 Risk that BSE infectivity is recycled and propagated

- Until 1994 the extremely/very unstable system would have recycled and propagated the agent, should it have been introduced. The risk that this happened is directly proportional to the external challenge – which is considered to be high until at least 1998.
- The introduced BSE infectivity could have exposed native cattle. Thus BSE-infectivity could have started to circulate in the system around the early 90s, got recycled and amplified and the disease could have been propagated.
- The resulting propagation risk reached high levels in the early 90s and remained at this level until 1998.
- The risk that incoming infectivity was recycled and propagated was significantly reduced in 1996 when the SRM ban on imports was introduced.
- The improvement in the rendering system, which has been achieved in mid-1998, has reduced the risk of recycling and propagating and prevents further amplification.

5. CONCLUSION ON THE GEOGRAPHICAL BSE-RISK

5.1 The current GBR

The current geographical BSE-risk (GBR) level is III, i.e. it is likely that domestic cattle are infected with the BSE-agent but it is not confirmed.

The current surveillance system is passive, i.e. depending on notification of suspects, and because of the intrinsic limitations of such systems not able to detect all clinical BSE cases. It is regarded to be possible that BSE will be confirmed in Spain within the next years, in particular if active surveillance would enhance the performance of the surveillance system.

5.2 The expected development of the GBR

- If the current measures continue to be well implemented, Spain could be seen to move, over time, into GBR level II because, as long as the system remains stable, the anticipated circulating BSE will continue to be slowly eliminated from the system and the GBR will, over time, decrease.

5.3 Recommendations for influencing the future GBR

- Excluding domestic SRMs (as foreseen in 2000/418/EC) and fallen stock from rendering will enhance the stability and speed-up the elimination of any BSE-risk from the country.

Expanding the surveillance system to target high-risk populations such as adult cattle in fallen dairy stock and adult cattle presented for emergency slaughter will improve the ability to identify and exclude from processing clinical and (some) pre-clinical BSE cases and hence increase the stability further. It would make detection of single cases of BSE more likely.
